ABSTRACT

Imagine you are facing a mirror, seeing at the same time both your real body and a virtual display of your brain in activity and perfectly superimposed to your real image “inside your real skull”. In this paper, we introduce a novel augmented reality paradigm called “Mind-Mirror” which enables the experience of seeing “through your own head”, visualizing your brain “in action and in situ”. Our approach relies on the use of a semi-transparent mirror positioned in front of a computer screen. A virtual brain is displayed on screen and automatically follows the head movements using an optical face-tracking system. The brain activity is extracted and processed in real-time with the help of an electroencephalography cap (EEG) worn by the user. A rear view is also proposed thanks to an additional webcam recording the rear of the user’s head. The use of EEG classification techniques enables to test a Neurofeedback scenario in which the user can train and progressively learn how to control different mental states, such as “concentrated” versus “relaxed”. The results of a user study comparing a standard visualization used in Neurofeedback to our approach showed that the Mind-Mirror could be successfully used and that the participants have particularly appreciated its innovation and originality. We believe that, in addition to applications in Neurofeedback and Brain-Computer Interfaces, the Mind-Mirror could also be used as a novel visualization tool for education, training or entertainment applications.

Keywords: Augmented Reality, EEG, Brain Activity, Mirror, Visualization, BCI.

1 INTRODUCTION

Nowadays ElectroEncephaloGraphy (EEG) and Brain-Computer Interfaces (BCI) provide a unique access to brain activity in real-time. This enables new kinds of applications such as “Neurofeedback” which consists in progressively learning to control a brain pattern while continuously observing a real-time feedback about this pattern [4]. Neurofeedback is considered today in the medical field for treating different kinds of pathology, such as attention deficits [11]. In most Neurofeedback applications, the feedback used is visual and consists in basic graphics such as 2D gauges increasing or decreasing over time. More elaborated visual feedback and 3D graphics can be used to display brain activity, but they are

generally used in off-line visualization software [22], for instance for medical diagnosis.

Figure 1: The Mind-Mirror prototype. Left: A virtual brain superimposed to the real user’s image (photomontage). Right: Our mirror-based augmented reality setup.

In this paper we study the combination of Augmented Reality (AR), 3D Visualization, and ElectroEncephaloGraphy. We introduce a novel setup called “Mind-Mirror” which enables the visualization of our own brain activity “inside our own head” by superimposition (see Figure 1-left). The brain activity is extracted in real-time using an EEG acquisition machine and is displayed in a mirror-based AR setup in front of the user’s skull in semi-transparency. The Mind-Mirror could therefore be used for entertaining or educational activities, or for Neurofeedback applications, i.e., training to control our brain while being in a more natural, engaging, and immersive environment.

The remainder of this paper is organized as follows. Section 2 describes related work on augmented reality and brain activity visualization. Section 3 introduces the Mind-Mirror system and details its main components. Section 4 presents a pilot study comparing the Mind-Mirror to a classical 2D visualization used in current Neurofeedback applications, in the context of controlling brain patterns related to concentration versus relaxation mental activities. The paper ends with a general discussion and a conclusion.

2 RELATED WORK

Since the beginning of augmented reality the properties of half-silvered screens have been used to superimpose various graphics on top of real objects. These objects could be buttons [7] or virtual enemies in a video game [19]. In both cases, displayed objects would seem very realistic to the user since they are superimposed over real objects. These virtual objects are not directly dependent on the mental state of the user. A recent paper has shown that a high quality display of flames and smoke on a user’s hand in AR could induce a heat sensation [21]. Thus the realistic display of a virtual stimulation on a body part seems to have a strong impact on the sensations of users.

Mirror-based systems have already been used to see virtual objects mapped on users in so-called “magic mirror” augmented re-

¶e-mail: anatole.lecuyer@inria.fr

ability [12]. For instance Maes et al. conceived the “Artificial Life Interactive Video Environment” (ALIVE) that allowed interaction between an autonomous virtual agent, e.g. a dog, and the real user. Users could perform gestures and see themselves in a magic mirror while the virtual agent would perform some actions depending on the gesture. In some cases, the mirror can be used to display virtual objects “inside” the user’s real body. For instance Blum et al. used a half-silvered mirror to show various organs “in situ” [3]. However, the displayed organs were static and not dependent on the state of the real organs, since no device was used to capture their activity.

The visualization of brain activity has been extensively studied, often by using recorded data and viewing offline the most active areas of the brain [2]. These active areas can be represented through a flat 2D map of the brain (using changing colors to show high- and low-activity zones) or a topography of surface activity [13]. However the existing approaches do not currently incorporate a direct user interaction.

In a recent study on Neurofeedback Hwang et al. used a real-time visualization of brain activity to train the user to BCI control [6]. Participants could visualize their cortical mu (8-12 Hz) rhythm activity in real-time, improving the BCI training and thus the performance when using the motor imagery paradigm. In this desktop setup participants were able to have a direct view of their brain activity using a simple 2D colored image of a virtual brain.

In the following section we introduce a novel approach relying on AR and 3D interaction for brain activity visualization in a magic-mirror setup.

3 THE MIND-MIRROR SYSTEM

3.1 Concept

The Mind-Mirror is an augmented reality paradigm that enables users to see in a mirror both their real head and a virtual display of their brain in activity and perfectly superimposed to their real head. In other words, when using the Mind-Mirror, users can see “through their own head”, visualizing their brain “in action and in situ”.

Our approach relies on the use of a semi-transparent mirror positioned in front of a computer screen. A virtual brain is displayed on-screen and automatically follows the head movements using an optical face-tracking system. The brain activity is extracted and processed in real-time thanks to an EEG cap worn by the user. Since a mirror alone can only show the frontal parts of the brain, we have also added a rear-view. This view uses a webcam placed behind and above the head of the user.

3.2 System Description

The Mind-Mirror system is composed of several components which are displayed in Figure 2:

- **EEG recording and amplification:** EEG acquisition and amplification is performed using a set of electrodes mounted on a cap (1) and an EEG amplifier (g.tec, g.USBamp) (4).
- **Webcam:** a webcam is used and positioned on a wall behind the user (2) in order to capture the image of the back of the head of the user and display it in a rear-view window on the Mind-Mirror.
- **Face and head tracking:** Face and head tracking are achieved using a Microsoft Kinect camera (3) and its development kit [14]. It is used to overprint the virtual brain at the position of the user’s head in real-time. The Kinect development kit uses here depth and color sensing of the camera to track the human face using proprietary algorithms.
- **Signal-processing:** Signal processing is done on a computer (5) using the OpenViBE software platform [20].

Figure 2: Mind-Mirror system overview. Components: (1) EEG cap, (2) webcam, (3) Microsoft Kinect camera, (4) g.tec g.USBamp EEG amplifier, (5) laptop PC, (6) computer screen, (7) half-silvered foil.

- **Display:** The display system consists in a computer screen (6) that supports a half-silvered foil (7) applied onto a thin plastic plate. Due to the half-silvered foil only the screen parts that are bright can be seen. The rest of the screen surface appears opaque and reflective, as with a classical mirror. Using a real mirror enables users to see themselves directly, which would not be possible with a camera-based AR setup.

EEG data acquired with OpenViBE software [20] and head movement data from the Kinect are retrieved and processed within a Unity3D-based application that simulates and displays the virtual brain. Virtual brain activity visualizations are displayed in real-time (framates between 25 and 80 Hz depending on the visualization type). Face-tracking and head movements are detected and processed with a latency of less than 500 ms.

3.3 Visualization Tools

As mentioned previously, the Mind-Mirror can be used to display the brain in action and “in situ”. Different visualization techniques can be used. We have explored the following ones for the Mind-Mirror.

3.3.1 Brain Topography

The brain topography visualization enables the display of the EEG signal power over the brain surface, as shown in Figure 3-left. This representation allows for a quick overview of the most active brain areas, i.e., the areas with the largest EEG signal power.

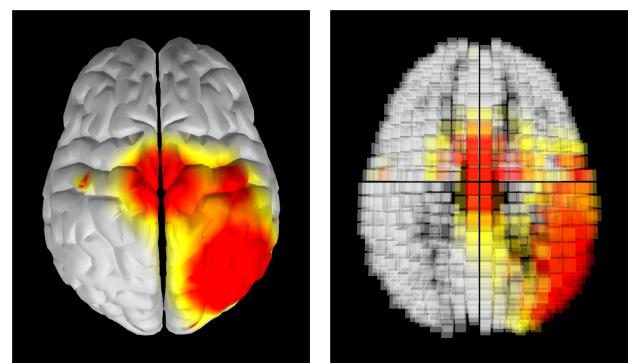

Figure 3: Brain visualization techniques. Left: topography display of surface brain activity. Right: volumetric display of brain activity using voxels. Red and yellow colors correspond to the high-activity spots.

3.3.2 3D Volumetric Representation Using Inverse Solution

EEG signals correspond to brain activity at the surface of the scalp. Fortunately, it is possible to estimate the brain activity in the whole brain volume using algorithms known as inverse solutions [17]. The volumetric brain activity hence estimated can then be displayed with a 3D model of the brain using voxels. This visualization allows for a comprehensive 3D view of the brain activity, as shown in Figure 3-right.

3.3.3 Visualization Integrating Mental State Classification

One of the main goals of BCI or Neurofeedback training applications is to help users gain control of their own brain activity, in order to be able to modulate it and reach a specific mental state, e.g., a relaxed or a concentrated mental state. Therefore, in such applications, it is important for users to be aware of the mental state identified by the system, so that they can identify the relevant features of their brain activity and learn how to control them.

Current brain activity visualization tools, e.g., the ones mentioned above, are not well suited for such purposes. Indeed, they do not show the mental state identified by the system, and display with equal focus the activity in the entire brain, making it difficult for the user to identify the relevant features in all the displayed information. In contrast, classical BCI feedback and Neurofeedback only show simple 2D graphics such as gauges [15], only indicating the mental state identified, without giving information about the underlying brain activity despite this being recommended for a successful learning [10].

Therefore, in this paper, we propose a new brain activity visualization technique that aims at using the best of both worlds. Indeed, our approach 1) gives information about the underlying brain activity, using surface topography, and highlights some specific brain areas that are relevant for the targeted mental state classification, and 2) displays simultaneously the mental state currently identified by the BCI, which altogether is expected to help users identifying the relevant features of their brain activity in order to control more efficiently the targeted brain activity. With this new representation, the whole virtual brain is colorized according to the mental state of the user, as identified by the BCI system. Currently, we have explored this approach with a BCI that estimates the concentration and relaxation level of the user (see Section 4). When the system detects that the user is relaxed, then the whole virtual brain is colored in blue, otherwise it is colored in red. Moreover, the more blue the brain is displayed, the more confident the BCI system is in the corresponding mental state estimation. This confidence is computed using the output of the linear regression used in the BCI system (see Section 4.1): the larger the absolute value of the linear regression output, the more confident the estimation [5]. Then, in order to help the user pay attention to the most relevant information and not overwhelm him, the most important brain areas for the estimation of the mental states are shown with a more intense color, as shown in Figure 4.

The most important brain areas were chosen using machine learning tools, as exposed in Section 4.1. In particular, the surface topography only displays the EEG signals in the frequency band that is the most relevant for classification (i.e., the most discriminative frequency band in the Filter Bank Common Spatial Pattern algorithm [1]), and only the most relevant channels (i.e., the channels with the largest absolute weights in the Common Spatial Patterns filters for this frequency band) are displayed with more intense colors.

Surface topography is displayed on a 3D mesh of a brain using vertex coloration. In our current simple implementation the surface topography is computed as follows. The color of vertex j (V_j) is defined using Equation (1). A state color S is defined as red if the detected mental state is concentrated, blue otherwise. Electrode Relevance (R_i) represents the relevance of the electrode i for

one mental state, computed during the initial calibration phase (see Section 4.3). P_i represents the EEG band power at electrode i and $D_{i,j}$ the distance between electrode i and vertex j . The electrode positions used are those of the international 10-20 system. Note that other computations could be used such as Surface Laplacians [20].

$$V_j = S * \sum_{i=1}^n \frac{R_i * P_i}{D_{i,j}} \quad (1)$$

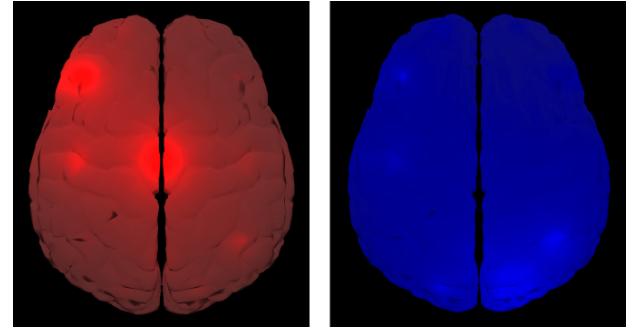

Figure 4: Brain activity visualization integrating concentration/relaxation classification. The left image corresponds to a concentrated mental state (red color) while the right image shows a relaxed state (blue color). A brighter color represents a more intense electrical activity.

3.3.4 Rear-View

The rear-view, which allows users to see what is happening on the rear parts of their brain, is displayed on top of our mirror (see Figure 5). This rear-view makes use of a standard computer webcam placed above and behind the user. Another virtual brain is used here and also superimposed over the image recorded by the webcam.

Figure 5: Rear-view window: a virtual brain is superimposed with the back of the user's head. It follows the orientation of the real user's head and enables the perception of what happens at the back of the head (brain).

4 PILOT STUDY

In order to assess our Mind-Mirror system, we performed a pilot study in which the participants used it as feedback in a BCI based on the concentration and relaxation levels. More precisely, with this BCI, participants had to put themselves in a relaxed or in a concentrated state, such mental states being analyzed and identified by the

BCI in real-time. These two mental states could then be assigned to two different commands (see, e.g., [5]), although this was not the case in this study. Here, we studied both the performance (in terms of successfully recognized mental state) and preference (using subjective questionnaires) of the participants using the Mind-Mirror to visualize their brain activity in real-time while using the BCI. We also compared the Mind-Mirror to a temporal gauge, a typical representation used within the BCI and neurofeedback community (see Figure 6). This indeed enabled us to study the impact of the more complex but also more immersive and informative brain activity representation that is the Mind-Mirror on participants' experience and BCI performance.

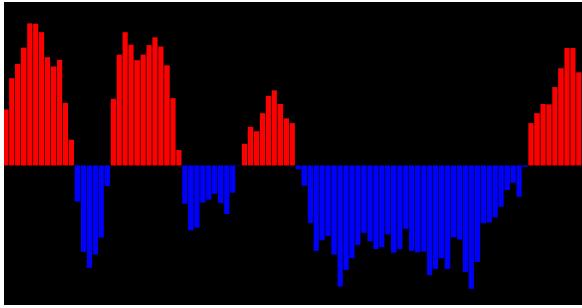

Figure 6: The temporal gauge display. The red and blue bars respectively represent the evolution of the concentration and relaxation levels in time.

4.1 Experimental Apparatus

The experiment was conducted in a room without environmental noise or other source of distraction. The participants were comfortably seated in front of a computer screen.

EEG signals were acquired with a sampling frequency of 512Hz using a 16-channels g.USBamp acquisition system. EEG were recorded at channel locations T7, T8, F7, F8, Fp1, Fp2, C3, Cz, C4, O1, O2, F3, F4, P3, Pz and P4 according to the international 10-20 system. The ground electrode was placed on position FCz, and the reference electrode on the participant's left earlobe.

The concentration level of each participant was estimated using a subject-specific model obtained with machine learning [5]. More precisely, the Filter-Bank Common Spatial Pattern (FBCSP) algorithms [1] was used to identify the most relevant EEG frequency bands and channels to discriminate the concentrated from the relaxed mental state [5]. Only frequency bands within the theta (4-7Hz) and alpha (8-14Hz) rhythms range were explored. Indeed, from a neurophysiological point of view, these rhythms are expected to be correlated with concentration [16], and are less likely than higher frequency bands to be contaminated by muscle artifacts [5]. The FBCSP algorithm was optimized on training EEG signals collected during the initial calibration phase (see Section 4.3 for details on this phase). Then, FBCSP features were used to train a linear regression algorithm to estimate the participant's concentration level. Once the BCI is calibrated in this way, it can be used online. To do so, the FBCSP features were extracted from the EEG signals over the last 2s (using a sliding window scheme, with a 0.1s overlap between consecutive windows) and used as input for the linear regression, which output indicates the participant's concentration level. More precisely, a negative (respectively positive) output value means that the participant is in a relaxed (respectively concentrated) mental state.

4.2 Population

Twelve participants (aged from 21 to 30, mean=25, sd=2.8) took part in the experiment.

4.3 Experimental Plan

A calibration phase took place before the experiment. Participants were asked to concentrate for 60 seconds and then relax for 60 seconds without having any visual feedback. Participants were free to choose any cognitive activity for the concentration task. Several suggestions were made such as a “mental computation” task. The EEG data collected during this phase were used to calibrate the signal processing pipeline.

Two different representations were then compared: the Mind-Mirror and the temporal gauge. As the participants were concentrating or relaxing, the brain activity representations would show the current level of concentration or relaxation, respectively.

The experiment was divided into 12 trials. Each trial comprised a relaxation phase followed by a concentration phase, each of them lasting 25 seconds. The experiment lasted 10 minutes per representation and so 20 minutes for the whole experiment. The two brain activity representations were used by each participant. The half-silvered foil was manually applied on the monitor screen for the Mind-Mirror condition, and taken away for the gauge condition. Participants were divided into two groups. The first group started with the Mind-Mirror and the second group started with the temporal gauge.

4.4 Collected Data

For each trial and each participant, we recorded the BCI classifier output values resulting from the signal-processing pipeline. At the end of the experiment and for each representation, participants had to fill out a subjective Likert-scale questionnaire (1: strongly disagree to 7: strongly agree). Questions were: “Do you think that the representation is *x*”, where *x* was one of the following criterion: (1) Comprehensible, (2) Motivating, (3) Simple, (4) Clear, (5) Innovative, (6) Original.

5 RESULTS

5.1 Classification performance results

We conducted statistical analysis in order to assess the BCI classification performance for each brain activity representation. To do so, we first compared the linear regression output between the relaxed state and the concentrated state for each of the two visualizations separately, in order to assess whether participants could control the BCI with them. A paired t-test showed significant differences in BCI output between the concentrated and relaxed states for the gauge visualization ($t(11)=-4.82$, $p=0.0005$) as well as for the Mind-Mirror visualization ($t(11)=-2.73$, $p=0.02$). We also compared the classification performances obtained with the two visualizations using a paired t-test. Such classification performances were assessed using the average difference between the linear regression output during the concentration and relaxation conditions, as in [5]. The larger the difference, the better the discrimination between the two mental states. We found no significant difference ($p=0.19$) between the classification performance with the Mind-Mirror condition (average difference: 0.31 ± 0.39) and the gauge condition (average difference: 0.46 ± 0.33), although there might be a slight trend towards better performances with the gauge. The average values of the linear regression output for each mental state are provided in Table 1.

5.2 Questionnaire Results

We performed a Wilcoxon test on the visual representations for the different criteria. We found a significant effect for 4 criteria: Simplicity ($z=-1.981$, $p=0.048$), Clarity ($z=-2.089$, $p=0.037$), Innovation ($z=-2.890$, $p=0.004$) and Originality ($z=-2.924$, $p=0.003$). The participants found the Mind-Mirror less simple, less clear but more innovative and more original than the gauge representation. Table 2 summarizes the questionnaire results for the 6 criteria.

Table 1: Classification performance results. Average values of the linear regression output and standard deviation are provided for each representation (Gauge; Mind-Mirror) and each state (Concentration; Relaxation), as well as the difference between the two states (Diff.)

	Gauge			Mind-Mirror		
	Con.	Relax.	Diff.	Con.	Relax.	Diff.
Mean	0.21	-0.25	0.46	-0.004	-0.31	0.31
SD	1.44	1.50	0.33	1.1	1.22	0.39

Table 2: Subjective questionnaire results for the 6 criteria (1: worst to 7: best). Average values of mark and standard deviation were provided for each representation.

	Gauge		Mind-Mirror	
	Mean	SD	Mean	SD
Comprehensibility	5.67	1.37	5.17	0.94
Motivation	4.75	1.05	4.67	1.37
Simplicity	5.92	1.68	4.92	1.31
Clarity	5.83	1.27	4.83	1.11
Innovation	3.17	1.11	5.5	1.09
Originality	3.25	1.14	5.5	0.8

6 GENERAL DISCUSSION

The results obtained from the classification analysis and from the questionnaires enabled us to assess the pros and cons of the Mind-Mirror.

Concerning the pros, results from the classification analysis suggested that the participants were able to put themselves in a concentrated or in a relaxed state with the Mind-Mirror representation, hence showing that participants can successfully use the Mind-Mirror as a feedback for a neurofeedback/BCI application. Results also suggested that the Mind-Mirror, even if more complex than a classical gauge, does not seem to lead to substantially lower BCI performance, although there might be a trend towards slightly better performance with the gauge. Further studies with a larger population would be required to confirm this point. Results from the questionnaire suggested that participants found the Mind-Mirror to be more original and innovative than traditional BCI feedback (i.e., the gauge). In other words, this means that the Mind-Mirror gives a higher quality experience than a gauge, with a more engaging feedback environment. Moreover, as compared to the gauge, the Mind-Mirror provides more information, since it indicates in real-time which brain areas are active. The participants quoted the Mind-Mirror as “clear and easy to understand”, “quite precise”, “gives a good indication of the activated zones, without being too complex”. The Mind-Mirror thus provides an explanatory feedback, informing about what is going on in the user’s brain, whereas the gauge only provides a corrective feedback, only indicating whether the user is correctly relaxed or concentrated. These two feedback properties, namely, being engaging and explanatory, are recommended properties for the efficient learning of a skill such as here learning how to control brain activity [10]. The evaluation reported in this paper is a short-term one, focused on feedback perception and usability. As such longer-term learning effects are unlikely to occur. In future works, it would be interesting to compare the classical gauge to the Mind-Mirror during multiple neurofeedback sessions, over multiple days. This would enable us to assess the users’ learning curves (i.e., performance improvements over time), and confirm whether the Mind-Mirror - due to its properties - can make learning faster and better as theoretically expected [10].

Concerning the Mind-Mirror cons, the user study highlighted that it was significantly more difficult to understand and to use than the classical gauge, at least for first-time users who qualified it as having a “slight lack of readability”. This result is not unexpected

since the Mind-mirror is a rich multidimensional feedback, thus a more complex one than the mono-dimensional gauge feedback. Users therefore need more time to get used to the Mind-Mirror feedback, to understand how it works and how to handle it. This may explain why the classification analysis revealed no increase in BCI performance with the Mind-Mirror. An alternative interpretation that could explain such performance is that the Mind-Mirror displays rich instantaneous information, but no temporal information, whereas the gauge displays an instantaneous information, more precisely the regression output, but also the previous outputs, hence showing a short history describing temporal variations. In the future it would be interesting to add this temporal information to the Mind-Mirror. This could be done, e.g., by displaying the last few surface topographies as well as the current one, with the older ones displayed in dimmer colors or steam-like appearance, and slowly fading away as time passes. It would also be interesting to perform a follow-up longer-term study, in order to assess users’ performance and preference once they got used to the Mind-Mirror principle. Still regarding possible improvements to the Mind-Mirror design, some participants reported that they enjoyed the mirror principle with AR (“easier to control the movement without interfering with the task”, “nice to look at and entertaining”), but that it made visually focusing on the brain or the user’s reflection more difficult (“the virtual brain appears on the foreground whereas the reflection seems to be on the background”). In the future, it could be relevant to compare this mirror AR approach to a more classical AR design with a webcam filming the user and overlaying the brain, without the use of a mirror. This would prevent users from looking at themselves into the eyes as in a real mirror but could make the brain activity display easier to watch and to focus on.

As mentioned earlier, the Mind-Mirror has the potential to be used for multiple other applications, notably education, entertainment and neurofeedback training. Indeed, the Mind-Mirror could have educational purposes, as a support tool to teach brain biology and anatomy. For instance, users could select the brain area they are interested in by pointing to it using their own hands. Hand tracking could be done using the Kinect, and much meaningful information could be displayed about the selected brain area. This could be an engaging and effective way to learn, for instance, the different brain lobes names, their locations as well as how the brain works.

The Mind-Mirror could also be used for entertainment, as a motivating feedback in BCI-based video games for instance [8]. It could also be used in serious games involving the brain, such as video games for brain fitness or for treating Attention Deficit Hyper Activity Disorders [9].

Finally, and maybe more importantly, the Mind-Mirror could be a very powerful tool for Neurofeedback training, either for medical applications or for BCI control. Actually, it could be used to train users to learn how to modulate the brain activity in some areas of their brain. Indeed, as we have exposed before, the visualization tools offered by the Mind-Mirror are engaging, rich and explanatory which, from an instructional design point of view, is expected to lead to efficient skill learning, e.g., a BCI skill [10]. The Mind-Mirror is thus expected to improve learning in BCI or neurofeedback applications in the long-term. We performed here a first short-term study with concentration and relaxation. In the future, it would be interesting to explore it with other BCI paradigms, e.g., with BCI based on imagination of movements [18].

7 CONCLUSION

In this paper we introduced the Mind-Mirror, a system which combines augmented reality and EEG in order to enable users to visualize their own brain operating inside their head. We proposed various brain activity visualization tools for this system, and identified multiple possible use-cases, including education, entertainment, neurofeedback and BCI. We also conducted a user study to

compare feedback provided using the Mind-Mirror to a classical gauge feedback in a BCI experiment. Results suggested that participants found the Mind-Mirror more innovative and engaging than the gauge although more complex to use and understand. This complexity did not lead to a statistically significant drop in BCI performance. Overall, the Mind-Mirror seems to be a promising tool for a variety of applications, which would benefit from being validated by further studies.

Future work will concern more evaluations of the Mind-Mirror for BCI and neurofeedback applications. This implies formal experiments in other application contexts (e.g., game or education), as well as further studies to identify the best display parameters (e.g., color maps, contrasts, use of the mirror, etc.) for an optimal visualization and learning experience.
